Model Comparison Approach

Recap

- We've compared a lot of means:
 - $\circ \;$ sample mean (\bar{x}) to population mean (μ); paired or not paired
 - \circ 2 sample means ($ar{x_1}$ vs. $ar{x_2}$)

This time

- *t*-tests through oneway ANOVA
- BUT, we're going to take a different approach...

Model Comparisons

Scenario 1

Gerrymandering

- Depending on the estimate you pick, about 53% of voters in Wisconsin were Democrats in 2016.
- So our best estimate of the percentage of voters that are Democrat in any *district* might be 53%
- Now that 2016 feels like a million years ago, you find that in actuality it was 52% of voters in Wisconsin were Democrats in 2016.
- Question: Was our population estimate of 53% significantly different from our sample estimate of 52%?

one-sample t-test

Model Comparisons

In the normal **one-sample** t**-test**

- $\bar{x} = \mu$
- $H_0: \bar{x} \mu = 0$
- $H_A: \bar{x} \mu \neq 0$

Model Comparisons

Another way of thinking about it -- what does a model of the null hypothesis look like?

- If there is truly no difference between means (the null is true), then the best way to summarize the data is to use the *population mean*. Let's use that as our **estimator**.
- If we use the population mean as our estimator, we can look at error or **residuals**. The actual data points estimator (a deviation score!). We want to do a good job of predicting. So we want this error to be as SMALL as possible!
- If there *is* a difference between means (the null should be rejected), then the best way of summarizing our data should be to use the sample mean.

Which had the smallest prediction error?

model that uses population mean as the estimator?

model that uses sample mean as the estimator?

Model Comparisons

Let's break it down into **full** and **restricted** models:

- Restricted Model: reflects what we are testing against.
- **Full Model:** allows us to fully include all information we might have.
- Size of the effect is calculated as the following:

$$rac{(E_r-E_f)/(df_r-df_f)}{E_f/df_f}$$

- ullet E_r is the error from the restricted model
- ullet E_f is the error from the full model
- ullet df_r is the degrees of freedom from the restricted model
- ullet df_f is the degrees of freedom from the full model

The Data

```
dems <- data.frame(Dem = c(30, 69, 99, 77, 29, 37, 38, 37))
dems
```

```
## 1 30
## 2 69
## 3 99
## 4 77
## 5 29
## 6 37
## 7 38
## 8 37
```

Step 1: Get the deviation scores. In the restricted model, we are subtracting from our population estimate of 53%. That is, 53% is our PREDICTION of the **restricted** model

```
dems$deviationScores <- dems$Dem - 53
dems</pre>
```

```
##
     Dem deviationScores
## 1 30
                      -23
## 2
     69
                       16
## 3
     99
                       46
     77
                      24
## 5
      29
                      -24
## 6 37
                     -16
## 7 38
                     -15
## 8
     37
                     -16
```

Step 2: Square the deviation scores

```
dems$dev2 <- dems$deviationScores ^2
dems</pre>
```

```
Dem deviationScores dev2
##
## 1
                    -23 529
    30
                     16 256
## 2
     69
## 3
     99
                     46 2116
                    24 576
## 4 77
## 5 29
                    -24 576
## 6 37
                   -16 256
## 7 38
                   -15 225
## 8 37
                   -16 256
```

Step 3: Get the sum of the square deviation scores. This is our **ERROR** term. It is the squared errors.

```
Er <- sum(dems$dev2)</pre>
dems
##
    Dem deviationScores dev2
## 1 30
                    -23 529
## 2 69
                     16 256
## 3 99
                     46 2116
## 4 77
                   24 576
## 5 29
                    -24 576
## 6 37
                   -16 256
## 7 38
                 -15 225
## 8 37
                   -16 256
Er
```

[1] 4790

Step 4: Determine the degrees of freedom.

- Degrees of freedom deals with how much information is free to vary
- You get a feel for this the more you practice
- In this restricted model, there is nothing that we are "guessing" or estimating. So there is nothing to subtract. df=n, ${\it df}=8$

```
dfr <- 8
```

Step 1: Get the deviation scores. In the full model, we are subtracting from our sample estimate of 52%. That is, 52% is the PREDICTION of the **full** model.

```
demsFull = dems %>%
  select(Dem)

demsFull$deviationScores <- demsFull$Dem - 52
demsFull</pre>
```

```
Dem deviationScores
##
## 1 30
                     -22
## 2
     69
                      17
## 3
     99
                      47
## 4
     77
                      25
## 5 29
                     -23
## 6 37
                     -15
## 7 38
                     -14
## 8 37
                     -15
```

Step 2: Square the deviation scores

```
demsFull$dev2 <- demsFull$deviationScores^2
demsFull</pre>
```

```
Dem deviationScores dev2
##
## 1
    30
                    -22 484
                     17 289
## 2
     69
## 3
     99
                     47 2209
                    25 625
## 4 77
## 5 29
                    -23 529
## 6 37
                   -15 225
## 7 38
                   -14 196
## 8 37
                   -15 225
```

[1] 4782

Step 3: Get the sum of the square deviation scores. This is our **ERROR** term. It is the squared errors.

```
Ef <- sum(demsFull$dev2)</pre>
demsFull
##
    Dem deviationScores dev2
## 1 30
                    -22 484
## 2 69
                     17 289
## 3 99
                     47 2209
## 4 77
                    25 625
## 5 29
                    -23 529
## 6 37
                    -15 225
## 7 38
                   -14 196
## 8 37
                    -15 225
Ef
```

16 / 62

Step 4: Determine the degrees of freedom.

- Degrees of freedom deals with how much information is free to vary
- You get a feel for this the more you practice
- In this full model, we are guessing/estimating our sample mean of 52. df=n-1, ${\it df}=8$ 1 = 7

```
dff <- 7
```

The Effect

$$\frac{(E_r - E_f)/(df_r - df_f)}{E_f/df_f}$$

```
effect <- ((Er - Ef) / (dfr - dff)) / (Ef/dff) effect
```

[1] 0.01171058

This is our F-statistic. $t^2=F$. So to get our t-statistic, let's take the square root of our effect.

```
tstat <- sqrt(effect)
round(x = tstat, digits = 3)</pre>
```

[1] 0.108

Model Comparison Approach

Is 0.108 more extreme than our critical value?

• For an $\alpha=.05$ in a two-tailed test with df=7, the critical t value is 2.3650.

Conclusion: No, it's not more extreme than the critical value. The weighted error term from the restricted model is smaller than the weighted error term from the full model -- 53 is a better estimator than 52. The means are not statistically significantly different

Model Comparison Approach

We just did a one-sample t-test! Let's verify our results:

```
##
## One Sample t-test
##
## data: dems$Dem
## t = -0.10822, df = 7, p-value = 0.9169
## alternative hypothesis: true mean is not equal to 53
## 95 percent confidence interval:
## 30.14892 73.85108
## sample estimates:
## mean of x
## 52
```

Scenario 2

- What if now we want to compare the difference in means (of % Democrats) between the 2010 election?
- Question: are the means of % Democrats significantly different between 2010 and 2016?

The Data

```
##
     Dem Year
## 1 30 2016
## 2 69 2016
## 3 99 2016
## 4 77 2016
## 5 29 2016
## 6 37 2016
## 7 38 2016
## 8 37 2016
## 9 30 2010
## 10 62 2010
## 11
      50 2010
## 12 69 2010
## 13 27 2010
## 14 29 2010
## 15 44 2010
## 16
      45 2010
```

The Hypotheses

- $\bullet \ H_0: \bar{x}_{2010} \bar{x}_{2016} = 0$
- $\bullet \ \ H_A: ar{x}_{2010} ar{x}_{2016}
 eq 0$
- Restricted Model: the best way of minimizing errors is to use the overall grand mean
- Full Model: the best way of minimizing errors is to use the group-specific mean

The Means

Let's get the grand mean to use in our Restricted model and the means of each group (% Dem in 2010 vs. % Dem in 2016):

```
grandMean <- mean(dems$Dem)</pre>
groupMeans <- dems %>%
  group_by(Year) %>%
  summarize(means = mean(Dem))
grandMean
## [1] 48.25
groupMeans
## # A tibble: 2 × 2
## Year means
## <fct> <dbl>
## 1 2010 44.5
## 2 2016
          52
```

```
dems$Mean <- rep(grandMean, times = nrow(dems))
dems</pre>
```

```
##
      Dem Year Mean
## 1
      30 2016 48.25
## 2
     69 2016 48.25

## 16 45 2010 44.5
                             0.5
                                    0.25
```

Step 4: Determine the degrees of freedom.

- Degrees of freedom deals with how much information is free to vary
- You get a feel for this the more you practice
- In this full model, we are guessing/estimating our 2 means (mean for 2010 and mean for 2016). df=n-2, $d\mathbf{f}=\mathbf{16}$ $\mathbf{2}$ = $\mathbf{14}$

```
dff <- 14
```

The Effect

$$rac{(E_r-E_f)/(df_r-df_f)}{E_f/df_f}$$

```
effect <- ((Er - Ef) / (dfr - dff)) / (Ef/dff) effect
```

[1] 0.4864114

This is our F-statistic. Remember that $t^2=F$. So to get our t-statistic, let's take the square root of our effect.

```
tstat <- sqrt(effect)
round(x = tstat, digits = 3)</pre>
```

[1] 0.697

Model Comparison Approach

Is 0.697 more extreme than our critical value?

• For an $\alpha=.05$ in a two-tailed test with df=14, the critical t value is 2.145.

Conclusion: No, it's not more extreme than the critical value. The weighted error term for the restricted is smaller than the weighted error term from the full. The grand mean was a better estimator than using individual group means. Therefore, the means are not statistically significantly different.

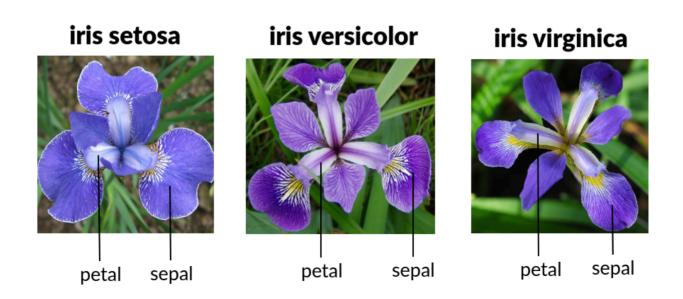

Model Comparison Approach

We just did an independent-samples t-test! Let's verify our results:

```
##
## Welch Two Sample t-test
##
## data: dems$Dem by dems$Year
## t = -0.69743, df = 11.406, p-value = 0.4995
## alternative hypothesis: true difference in means between group 2010 and group 20
## 95 percent confidence interval:
## -31.06632 16.06632
## sample estimates:
## mean in group 2010 mean in group 2016
## 44.5 52.0
```

Scenario 3

- We have a dataset that looks at the lengths and widths of petals & sepals of the iris flower. It includes 3 different species of irises.
- Question: are the sepal lengths different amongst the 3 species of irises?

The Data

```
Sepal.Length Species
                                               Sepal.Length
                                                                 Species

## 109
## 110
                 7.2 virginica
```

Reorder the data for teaching purposes

```
iris_sorted = iris %>%
  group_by(Sepal.Length, Species) %>%
  arrange(Sepal.Length)
```

The Hypotheses

- ullet $H_0:ar{x}_{setosa}=ar{x}_{versicolor}=ar{x}_{virginica}$
- $H_A: ar{x}_{setosa}
 eq ar{x}_{versicolor}
 eq ar{x}_{virginica}$
- Restricted Model: the best way of minimizing errors is to use the overall **grand mean**
- Full Model: the best way of minimizing errors is to use the group-specific means

The Means

Let's get the grand mean to use in our Restricted model and the means of each group:

```
grandMean <- mean(iris$Sepal.Length)</pre>
groupMeans <- iris %>%
  group_by(Species) %>%
  summarize(means = mean(Sepal.Length))
grandMean
## [1] 5.843333
groupMeans
## # A tibble: 3 × 2
## Species means
##
   <fct> <dbl>
## 1 setosa 5.01
## 2 versicolor 5.94
## 3 virginica 6.59
```

```
Sepal.Length Species
##
                         Mean
## 1
            5.1 setosa 5.843333

            6.3 virginica 6.588 -0.288 0.082944
## 104
```

Step 3: Sum of Squares -- our **ERROR** term

```
Ef <- sum(full$dev2)
Ef</pre>
```

```
## [1] 38.9562
```

Step 4: Determine the degrees of freedom.

- Degrees of freedom deals with how much information is free to vary
- You get a feel for this the more you practice
- In this full model, we are guessing/estimating our 3 means (mean for each species). df=n-3, ${\it df}=150$ 3

= 147

dff <- 147

The Effect

$$rac{(E_r-E_f)/(df_r-df_f)}{E_f/df_f}$$

```
effect <- ((Er - Ef) / (dfr - dff)) / (Ef/dff)
effect
```

[1] 119.2645

This is our F-statistic. This is an ANOVA, so we can stick with the F-statistic. (back to this in a sec)

```
round(x = effect, digits = 3)
```

[1] 119.265

Model Comparison Approach

Is 119.265 more extreme than our critical value?

The critical value for this test is 3.058

Conclusion: The weighted error term of the restricted is larger than the weighted error term of the full. Using each group's mean was a better estimator, compared to the overall grand mean. Therefore, the means are statistically significantly different.

Model Comparison Approach

We just did a oneway ANOVA! Let's verify our results:

Linking Distributions

- ANOVA is a comparison of means. But we are interested in variance. That is, we are trying to figure out the source of the variance (more on this next time)
- When we want to make inferences about sample variability, we need to know the sampling distribution.
- We can make use of the χ^2 distribution here. It has a single parameter, ν , related to the sample size, N. There is an important relationship between the normal distribution and the χ^2 distribution:
 - The sum of squared standard normal variables will have a χ^2 distribution.

Linking Distributions

- The F-distribution is a ratio of two χ^2 variables -- 2 different variances
- However, it's weighted by degrees of freedom. But there needs to be a df for the numerator AND df for the denominator
- ullet So the F-distribution has 2 parameters: 2 different degrees of freedom. As we've talked about it thus far, think of this as the df for the full and restricted models. Next time, we'll translate into ANOVA terminology

$$F_{
u_1
u_2}=rac{rac{\chi^2_{
u_1}}{
u_1}}{rac{\chi^2_{
u_2}}{
u_2}}$$

The F-distribution is one-sided (like the χ^2). You only care about the upper tail. You can't have a negative variance. If this is the ratio of 2 variances (ish), it's not going to be negative (F-statistic ≥ 0)

The t, χ^2 , and F distributions all depend on the normal distribution assumption. The normal distribution is the "parent" population.

As sample size increases, t and χ^2 converge on the normal. F converges on : $\frac{\chi^2_{\nu_1}}{\nu_1} \text{ with the numerator depending on the normal}$

But keep in mind

These probability distributions have a key assumption:

the sample is a random selection from the population

If the sample is not a random selection, the rules of probability don't apply.

Utility

Why do this painful process?

A model is what **YOU** define. It's how you think the world works. The restricted model is really just an embodiment of the null hypothesis! The full model is the embodiment of the alternative hypothesis!

Minimizing error terms is how we evaluate multitudes of models!

All models are wrong, but some are useful - George Box

Plus, model comparison frameworks come up more formally in some advanced types of statistics.

Next time

Translate all of this into classic, textbook ANOVA terminology
